

Most of the published low bump was the normalisation

worst χ^2/dof of the four track fits in the pair

`make\_pair\_qa\_figures\_hist` returned $n/\text{tot}/np.\text{diff}(\text{edges})$ on GEOMETRIC edges, so each bin was divided by a linear width that grows with χ^2/dof and the left of the axis was lifted about 5× relative to the peak. Only 5.3 % of A-A pairs are below $\chi^2/\text{dof} = 5$ (C-C 1.5 %, D-D 0.8 %), so the A-specific excess is real and worth the investigation — but it is a shoulder, and the figure rendered it as a co-equal mode. All five log-scaled panels of that set carried the same lift. FIXED 2026-09-12: `\_hist` now returns the per-bin fraction, which is what its y-axis label always claimed; the right-hand panel is what the set draws today.
