

The test, declared before it was run

PRELIMINARY

if the dip at $u \approx +7$ mm is the trigger's, it must vanish when another arm does the triggering — except where the chamber is genuinely blind

Depth = $1 - (\text{occupancy per live cell in } -16 \dots 32 \text{ mm}) / (\text{the same in the two flanks})$, read only at $|v| < 152$ mm so the bar-length cut cannot leak in, and with hot channels masked in both samples alike. Chamber A has no dead runs; C has ~10 dead channels and D ~130, both under this window (STATUS.md, 2026-09-08). A's dip inverts because the beam itself illuminates the centre more — which is what the trigger had been carving a hole in. Chamber B has no trigger-matched bar: no angle, no match.
